## Abstract

$\text{U}_3\text{Si}_2$  is a candidate as an **advanced** fuel for light water reactors (LWRs). Compared to standard  $\text{UO}_2$  fuel, there are significant data gaps for the thermophysical and thermomechanical properties of  $\text{U}_3\text{Si}_2$ . Point defect concentrations and mobilities under irradiation govern a number of important fuel performance properties, such as creep and fission gas release. In this work, we employed literature density functional theory (DFT) data to inform a cluster dynamics framework to predict point defect concentrations in  $\text{U}_3\text{Si}_2$  under irradiation. Molecular dynamics (MD) simulations have been used to examine the contribution of atomic mixing during ballistic cascades to diffusion, as well as the diffusivity of U and Si at grain boundaries. These atomic scale models for diffusivity were then used to inform a creep model based on bulk (Nabarro-Herring) and grain boundary (Coble) diffusional creep and climb-limited dislocation creep. The model compares well against available experimental data and has been implemented in the BISON fuel performance code. A demonstration case using simple power profiles has been carried out, showing that negligible creep occurs due to the low temperatures experienced by  $\text{U}_3\text{Si}_2$  in-reactor; a consequence of its high thermal conductivity.

---

## 1. Introduction

Nuclear fuel must operate within well-defined criteria under the extreme conditions created within a reactor. During its lifetime, nuclear fuel undergoes significant compositional change as it is exposed to high levels of radiation damage, and experiences an extreme heat flux (due to fission and decay heat). The latter, in combination with the poor thermal conductivity of  $\text{UO}_2$  (especially at high burnup), creates extreme temperature gradients in standard  $\text{UO}_2$  fuel. As such, despite the high melting point of  $\text{UO}_2$ , the possibility of centerline melting is a concern during accident conditions. Fuels that exhibit higher thermal conductivity benefit from a reduced risk of fuel melting. Typically materials without a bandgap, such as uranium intermetallics, are suitable due to high electronic heat transfer.

Uranium silicide compounds have been widely used in low temperature research reactors, often as dispersion fuels within an aluminum matrix [1–6].  $\text{U}_3\text{Si}_2$  has replaced the more uranium dense  $\text{U}_3\text{Si}$  due to its reduced in-pile swelling [7–14]. More recently,  $\text{U}_3\text{Si}_2$  has been considered as an accident tolerant fuel candidate for light water reactors (LWRs) due to its high thermal conductivity [15], while also exhibiting higher uranium density than standard  $\text{UO}_2$  fuel. While these properties highlight the potential benefits of  $\text{U}_3\text{Si}_2$  as an LWR fuel concept, work must be done to address the reaction of  $\text{U}_3\text{Si}_2$  with steam [16, 17]. Another important

factor for fuel safety is the creep of the pellet, which impacts the stress imparted on the clad by the pellet, as well as the pellet-clad gap, which governs the gap conductance, thereby influencing pellet temperatures. Therefore, understanding the underlying processes mediating creep in advanced fuels, such as  $\text{U}_3\text{Si}_2$ , is critical to understanding the extent of their accident tolerance.

Diffusional creep has two contributions: i) bulk diffusion (Nabarro-Herring creep [18]) and ii) grain boundary diffusion (Coble creep [19]). Both of these processes are driven by the effect of stress on the point defect flux within the medium. Vacancies migrate away from tensile regions towards compressive regions, where the vacancy formation energy is lower. Conversely, interstitials migrate away from compressive regions towards tensile regions, where the interstitial formation energy is lower. In both cases, this results in net self-diffusion from the compressive to the tensile region, leading to diffusional creep.  $\text{U}_3\text{Si}_2$  creep models have previously been derived from experimental data [20]. Alternatively, by quantifying the equilibrium and non-equilibrium defect concentrations and associated migration barriers in the bulk lattice or in the grain boundaries (e.g. from atomic scale simulations), one could parameterize a constitutive model accounting for temperature dependent contributions of both Nabarro-Herring and Coble creep mechanisms. Additionally, climb-limited dislocation creep is rate limited by the current of point defects to the dislocation core. Thereby, a detailed study of the thermodynamics and kinetics of point defects has the potential to yield a constitutive model accounting for all three aforementioned diffusion-mediated creep mechanisms.

Atomic scale simulations have proven effective at giving insight into the underlying processes that govern diffusion in  $\text{UO}_2$  fuel [21–25]. There are three diffusion regimes for Xe and U in  $\text{UO}_2$  under irradiation that we also expect to be important for diffusion in  $\text{U}_3\text{Si}_2$ : i) thermal equilibrium diffusion ( $D_1$ ), ii) irradiation-enhanced diffusion ( $D_2$ ), and iii) athermal irradiation-induced diffusion due to atomic mixing during damage events ( $D_3$ ). Density functional theory (DFT) calculations give a good comparison to experiments on  $\text{UO}_2$  for  $D_1$  [21–23]. By using the DFT data from Perriot et al. [23] to parameterize a cluster dynamics model, Matthews et al. [24, 25] were able to simulate the  $D_2$  diffusion regime for Xe and U self-diffusion in  $\text{UO}_2$  [24]. Classical MD simulations of irradiation damage processes have been employed to study the athermal  $D_3$  diffusion regime of self and Xe diffusion in  $\text{UO}_2$  [26–28]. To support the development of accident tolerant fuel performance codes, for which limited experimental data exist, the same mix of atomic scale simulation techniques can be applied to predict defect diffusion in  $\text{U}_3\text{Si}_2$ . Andersson et al. have already used DFT to derive parameters for U and Si defect stability and  $D_1$  diffusion in  $\text{U}_3\text{Si}_2$  [29]. By studying  $D_1$ , they generated all the defect energy data necessary to parameterize the cluster dynamics framework of Matthews et al. [24, 25] for the study of  $D_2$  diffusion in  $\text{U}_3\text{Si}_2$ .

In this work, cluster dynamics simulations for  $\text{U}_3\text{Si}_2$  have been developed to predict point defect concentrations and diffusivities for in-reactor conditions. MD simulations, employing the Beeler U-Si potential [30], have been used to simulate athermal contributions to self-diffusion through ballistic cascades in the bulk lattice, as well as the diffusivity of U and Si at grain boundaries. These atomic-scale diffusivity data have then been combined to develop a lower length scale (LLS) informed model for Nabarro-Herring, Coble, and climb creep of  $\text{U}_3\text{Si}_2$ . The model was validated against available literature experimental data and has been implemented in the BISON fuel performance code to demonstrate its application for  $\text{U}_3\text{Si}_2$  fuel using simple power profiles for steady-state and loss of coolant accident (LOCA) conditions.

## 2. Method

### 2.1. Cluster dynamics simulations

Single-point cluster dynamics simulations were carried out using the Centipede code developed by Matthews et al. [24, 25]. The framework has been applied to the simulation of defect concentrations and diffusivities contributing to self-diffusion [24] and Xe diffusion [25] in  $\text{UO}_2$  under irradiation, capturing the  $D_1$ - $D_2$  transition for self- and Xe diffusion. A detailed description of the framework can be found elsewhere [24, 25], however a brief description of the method and its application to  $\text{U}_3\text{Si}_2$  will be given here.

The concentrations of defects in the system are calculated by solving a set of ordinary differential equations (ODEs) that capture a number of phenomena including: production of Frenkel pairs through irradiation, mutual recombination of Frenkel pairs, interaction with sinks, and clustering of point defects. For a given defect,  $x_d$ , the ODE can be expressed as:

$$\frac{dx_d}{dt} = \dot{\beta}_d + \sum_C \dot{R}_{d,C}(x_d, x_C, T, G) - \sum_s \dot{S}_{d,s}(x_d, x_s, T, G) \quad (1)$$

where  $\dot{\beta}_d$  describes the source rate of defects through irradiation.  $\dot{R}_{d,C}$  and  $\dot{S}_{d,s}$  are the cluster and sink rates, which are summed across individual cluster and sink types, respectively. The Centipede code finds the steady-state solution to this coupled set of ODEs, such that  $\frac{dx_d}{dt} \leq \mathcal{R}$  for all defects, where  $\mathcal{R}$  is a convergence criteria. An individual reaction,  $\dot{R}_d$ , can be expressed as:

$$\dot{R}_d = \begin{cases} \frac{k_f^2}{\Omega} D x_A x_B \left[ 1 - \exp\left(\frac{f}{k_B T}\right) \right], & \text{if } f < 0, \\ \frac{k_r^2}{\Omega} D x_Y x_Z \left[ \exp\left(\frac{f}{k_B T}\right) - 1 \right], & \text{otherwise} \end{cases} \quad (2)$$

where  $\Omega$  is the atomic volume,  $k_i$  is a reaction rate constant,  $D = D_A + D_B$  is the sum of the diffusivities of the reactants (labeled A and B),  $x_A$  and  $x_B$  are the concentrations of the reactants and  $x_Y$  and  $x_Z$  are the concentrations of the products (labeled Y and Z). If  $f < 0$  the net rate is for the reaction to go forwards and otherwise it goes backwards. The driving force is given by the change in the free energy of the system due to the reaction:

$$f = \sum_{p \in P} \frac{\partial G}{\partial x_p} - \sum_{r \in R} \frac{\partial G}{\partial x_r} \quad (3)$$

where  $P$  and  $R$  are the set of products,  $p$ , and reactants,  $r$ , respectively.  $G$  is the total free energy of the system, such that the partial derivatives in Eq. (3) are dictated by the free energy of formation of the reactant and products, as well as the configurational entropy associated with their concentrations. Therefore, the key parameters needed to apply the Centipede code to  $\text{U}_3\text{Si}_2$  are the defect formation energies and entropies, which define the driving force of various reactions, and the diffusivities of the defects, which, along with the driving force, determine the reaction rates.

Here, this framework has been applied to the simulation of irradiation-enhanced defect concentrations and diffusion in  $\text{U}_3\text{Si}_2$ . One of the key differences with the original application to  $\text{UO}_2$  is that, due to the relatively low mobility of U and Si vacancies, the defect concentrations on both the U and Si sublattices must be tracked. Conversely, in the  $\text{UO}_2$  system both interstitials and vacancies on the oxygen sublattice migrate so quickly that interaction with sinks and mutual recombination maintains thermal equilibrium concentrations. Given that two sublattices are tracked, there are now three dependent variables that represent the perfect lattice

sites:  $U_U$ ,  $Si_{Si}$ , and  $V_i$ . Given that they are immobile, antisite defects are omitted to limit the number of solved variables and ODEs. The following reactions are solved for:

**Reactions of U and Si defect with sinks**

**Annihilation of interstitials and vacancies**

where standard Kröger-Vink notation has been used [31] but with charges omitted due to the system having metallic bonding. Clustering of point defects has been omitted due to the lack of available DFT data for vacancy or interstitial clusters. Radiation damage is accounted for by a source term for Si and U Frenkel pairs that is unchanged from those used for  $V_U$  and  $U_i$  in the application of Centipede to  $UO_2$  [24, 25]. This assumes that defect production due to fission in  $UO_2$  and  $U_3Si_2$  are approximately equal, which due to a lack of more specific information is a reasonable assumption. Similarly the sink terms used for  $V_U$ ,  $U_i$ ,  $V_{Si}$ , and  $Si_i$  are unchanged from the application to  $UO_2$  [24, 25]. This assumes that grain boundaries, dislocations, bubbles, and voids acting as sinks result in similar aggregate behavior in  $U_3Si_2$  as in  $UO_2$ . Future work should explore this assumption in more detail.

The defect stabilities and mobilities determine the behavior of the defects during the cluster dynamics simulations. The thermodynamic stability of the defects is given by the formation enthalpies and entropies taken from Andersson et al. [29], and are summarized in Table 1. The  $U_3Si_2$  system contains two symmetrically unique uranium lattice sites. To simplify the cluster dynamics simulation, only the most stable  $V_U$  site (2a) was considered for the total  $V_U$  concentration. Previously, the concentrations had been treated as per site values [29]. However, for the purposes of the cluster dynamics simulations it is important to account for the fact that there are not the same number of sites available to each defect in a given volume. Therefore, the concentration of the defects have been adjusted to account for the number of sites per formula unit,  $n$ . Under thermal equilibrium in the dilute limit, the defect concentration,  $[x]$ , of defect  $x$  is given by the Arrhenius function:

$$[x] = n \cdot \exp\left(\frac{-H_f + S_f T}{k_B T}\right) \quad (10)$$

where  $H_f$  is the enthalpy of formation,  $S_f$  is the entropy of formation,  $k_B$  is the Boltzmann constant, and  $T$  is the temperature.

In addition to the thermal stability defined by  $H_f$ ,  $S_f$ , and  $n$ , the diffusivity of individual defects,  $D_x$ , must be known in order to determine the irradiation-enhanced defect concentrations. This is defined by the defect migration barrier ( $H_{mig}$ ), attempt frequency ( $v_{mig}$ ), number of jump directions ( $Z$ ), the jump distance ( $\alpha$ ), and the dimensionality of diffusion ( $\xi$ ), as such:

$$D_x = \frac{Z}{2\xi} \alpha^2 v_{mig} \exp\left(\frac{-H_{mig}}{k_B T}\right) \quad (11)$$

In  $U_3Si_2$  there are two unique crystallographic directions for diffusion. For defining the rates within the cluster dynamics framework the fastest of the two directions for each defect was taken from Andersson et al. [29] and the relevant parameters are summarized in Table 2.

**Table 1:** Point defect formation energies and entropies, from Andersson et al. [29], used in the cluster dynamics model.

Defect	$H_f$ (eV)	$S_f$ ( $k_B$ )	$n$
$U_i$	0.87	-3.15	2
$V_U$	1.69	0.45	1
$Si_i$	0.55	2.19	1
$V_{Si}$	1.79	6.28	2

**Table 2:** Parameters that describe the defect diffusivities, from Andersson et al. [29], used in the cluster dynamics model.

Defect	$H_{mig}$ (eV)	$v_{mig}$ (Hz)	$\alpha$ (Å)	$\xi$	$Z$
$U_i$	0.31	$1.51 \times 10^{14}$	3.80	2	4
$V_U$	1.21	$1.40 \times 10^{13}$	3.90	1	2
$Si_i$	1.80	$1.00 \times 10^{13}$	5.18	2	4
$V_{Si}$	2.37	$1.00 \times 10^{13}$	4.19	2	4

## 2.2. Molecular dynamics simulations

### 2.2.1. Potential model

MD simulations were carried out using the Large-scale Atomic/Molecular Massively Parallel Simulator (LAMMPS) code [32]. The description of U-Si and Si-Si interatomic forces is given by the modified embedded atom method (MEAM) potential developed by Beeler et al. [30] and was developed to be used with the U-U interactions derived by Moore et al. [33]. The potential was fitted to structural properties, phase stability, elastic constants, and defect formation energies for various uranium silicide compounds. A particular focus was given to the accurate description of the properties of  $U_3Si_2$ . Beeler et al. [30] demonstrated the stability of the potential for 1 keV ballistic damage cascades.

### 2.2.2. Athermal diffusion

For the damage cascade simulations, a large  $U_3Si_2$  supercell, consisting of a  $30 \times 30 \times 50$  extension of the unit cell, was used to restrict the possibility of the cascade overlapping the periodic boundaries. The system was equilibrated at 600 K for 15 ps in the NPT ensemble at zero pressure, using Nosé-Hoover barostat and thermostat relaxation times of 0.1 ps and 0.5 ps, respectively, and a 2 fs timestep. During the final 5 ps of equilibration the cell dimensions were averaged. The final equilibrated system was re-scaled and fixed to the averaged cell dimensions to mitigate volumetric fluctuations and was then used as the starting point for subsequent damage simulations.

Cascade simulations were carried out in the NVE ensemble using the supercell dimensions that were equilibrated at 600 K. The cascades were initialized by selecting a U atom at random and scaling its velocity in a random direction with a kinetic energy of 1 keV, 2 keV, or 3 keV. Given the high atomic velocities involved, control of the timestep is necessary to ensure accurate integration over the potential energy surface. Sufficient numerical accuracy has been defined so that the total energy of the system is constant between timesteps, thus, satisfying the law of conservation of energy. To achieve this a 0.001 fs timestep was used for the first 0.5 ps, followed by 0.003 fs for 3 ps, then 0.01 fs for 10 ps, and 0.1 fs for the remaining 16.5 ps. These are notably small timesteps even for a cascade simulation and indicate a potential energy

surface for  $U_3Si_2$  with which care should be taken to ensure accurate integration. For PKA energies of 4 keV and greater, the required timestep became small enough to make the cascade simulations too computationally challenging. The cascades were repeated 3 times for each PKA energy with a different random PKA direction taken each time. The MSD was averaged over the final 15 ps and over the 3 repetitions to determine the MSD as a function of PKA energy. Although the temperature was not sufficiently high for intrinsic diffusion, the atomic vibrations of bulk atoms at their original sites made a non-negligible contribution to the MSD. Therefore, the MSD due to atoms moving from their initial positions but remaining in same potential well (atomic site) was calculated for the system at 600 K and subtracted from the MSD in the cascade simulations.

### 2.2.3. Grain boundary diffusion

MD simulations were used to study self-diffusion at grain boundaries. The objective of these simulations was to get a first estimate of the differences in diffusivities at the grain boundary, as opposed to the bulk, to ensure our final creep model accounts for a broad range of phenomena. Therefore, only a single grain boundary has been studied here and future work may consider a more comprehensive set of grain boundaries. A  $\Sigma$ -530 tilt grain boundary structure was used with a grain size of 83.6 nm. To ensure sufficient statistics, a supercell consisting of 480,000 atoms was created by extension in the directions parallel to the grain boundary. The system was equilibrated at the temperature of interest (1200 K to 1600 K at 100 K intervals) for 15 ps in the NPT ensemble at zero pressure, using barostat and thermostat relaxation times of 0.1 ps and 0.5 ps, respectively, and a 1 fs timestep. The supercell dimensions were averaged over the final 5 ps. By fixing the supercell at the averaged dimensions, the system was allowed to continue evolving in an NVT ensemble at the temperature of interest for 2 ns, during which the MSD of U and Si atoms was computed. As discussed in greater detail in Section 3.2, the slope of the MSD as a function of time for the final 1 ns was used to calculate the diffusivities of U and Si at the grain boundary. Two defective grain boundary supercells, where 0.34 % of the Si or U atoms were deleted at random, were also examined, however, only a negligible effect on the diffusivity was noticed. This indicates that the grain boundary diffusivity was not sensitive to vacancies and that bulk vacancy diffusion was far less significant than the contribution from U and Si atoms in the grain boundary itself.

### 2.3. BISON simulations

Here, a small 10-pellet fuel rodlet was analyzed. The cladding is taken as Zircaloy-4. The rodlet was modeled using a 2D-RZ axisymmetric representation of the fuel and cladding. Tabel 3 lists the geometry of the rodlet, initial conditions of the fill gas, and the operational conditions of the coolant (representative of a PWR). The initial value of grain-size for the  $U_3Si_2$  fueled rodlet was chosen based upon the observations from Shimizu's data upon which the coupled swelling model was developed [34]. The power supplied to the fuel was linearly increased from zero to its maximum value over 10,000 seconds for the fresh fuel cases. A maximum power rating of 35 kW/m was tested for steady state conditions. This higher power was selected due to the high thermal conductivity of  $U_3Si_2$ . It was then held at the maximum values for 3.2 years. The LLS-informed creep model developed in Section 3.3 was used.

In addition to the baseline cases using constant power, the behavior during a LOCA was also tested. To simulate a LOCA following the initial base irradiation, the fuel was subjected to a temperature transient applied to the outer cladding surface that was consistent with furnace tests completed at Studsvik [?] (Kyle, can you provide this reference?). An axial temperature profile of  $20\sin(x\pi/L) + T_{in}$  was applied, whereby  $x$  is the axial position,  $L$  is the rod length, and

$T_{in}$  is the inlet temperature, such that the peak temperature is 20 K higher than at the ends of the rod. This profile provides the driving force for ballooning of the cladding.

**Table 3:** Rodlet specifications for normal operation simulation

	Value	Units
Number of pellets	10	-
Fuel enrichment	5	%
Pellet length	9.83	mm
Pellet outer diameter	8.19	mm
Radial gap width	82.55	$\mu\text{m}$
Clad thickness	0.572	mm
Rodlet diameter	9.5	mm
Initial fill pressure	2	MPa
Initial fill gas	Helium	-
Plenum height	26	mm
Initial fuel grain radius	25	$\mu\text{m}$
Coolant inlet mass flux	3800	$\text{kg}/\text{m}^2\text{-s}$
Coolant inlet temperature	580	K
Coolant pressure	15.5	MPa

### 3. Results and Discussion

#### 3.1. Bulk self-diffusion

There are three possible contributions to the diffusion of point defects in bulk  $\text{U}_3\text{Si}_2$ : i) thermal equilibrium diffusion ( $D_1$ ), ii) irradiation-enhanced diffusion ( $D_2$ ), and iii) athermal atomic mixing during cascades ( $D_3$ ). The diffusion of point defects under thermal equilibrium conditions ( $D_1$ ) has been studied by Andersson et al. [29]. In Section 3.1.1, we show the results of implementing the point defect stabilities and diffusivities from Andersson et al. [29] in cluster dynamics simulations to predict irradiation-enhanced diffusion ( $D_2$ ). In Section 3.1.2, results are shown from MD simulations of ballistic cascades to examine the athermal contribution of atomic mixing to diffusion ( $D_3$ ).

##### 3.1.1. Thermal equilibrium $D_1$ and irradiation-enhanced $D_2$ diffusion

In this section the Centipede cluster dynamics code of Matthews et al. [24, 25] has been applied to investigate the  $D_2$  regime in  $\text{U}_3\text{Si}_2$ , where thermally activated diffusion is mediated by irradiation-enhanced defect concentrations. The defect free energies are defined by the DFT data calculated by Andersson et al. [29], which includes the energies of all reactions involved in the cluster dynamics model (as shown in Eqs. (4) to (9)).

The concentrations of  $V_U$ ,  $U_i$ ,  $V_{Si}$ , and  $Si_i$  under irradiation conditions, assessed using cluster dynamics, are shown in Fig. 1. At high temperatures, all defects are at their thermal equilibrium concentrations and  $Si_i$  are highest in concentration followed by  $V_{Si}$ , then  $U_i$ , then  $V_U$ . As the temperature decreases, irradiation-enhancement of first  $V_{Si}$  (<870 K), then  $V_U$  (<700 K), and then  $Si_i$  (<650 K), occurs. These enhanced concentrations will influence the low temperature creep rate, as studied in Section 3.3. The concentration of  $U_i$  does not undergo irradiation-enhancement. This is due to its very low migration barrier of 0.31 eV, which ensures it has a sufficiently high mobility to annihilate with  $V_U$  and sinks even at the lowest temperature studied here.

**Figure 1:** The irradiation-enhanced point defect concentrations in  $U_3Si_2$  from cluster dynamics simulations.

**Figure 2:** The contribution due to various point defects to irradiation-enhanced self-diffusivity in  $U_3Si_2$  from cluster dynamics simulations. The results include contributions from  $D_1$  and  $D_2$  type diffusion.

By converting the defect concentrations shown in Fig. 1 to per U atom and per Si atom quantities and then multiplying by the diffusivities of the defects in the fastest crystallographic direction (given by Eq. (11) and the parameters in Table 2), the contributions from different point defects to U and Si self-diffusivity have been determined, as shown in Fig. 2. As expected from previous work [29], it can be seen that the self-diffusivity due to interstitials is much greater than that due to vacancies. Additionally, the irradiation-enhanced regime is broadly athermal, except for the lowest temperature studied (600 K). Correlations based on the data

**Figure 3:** The MSD of U (blue) and Si (orange) as a function of time during a 3 keV damage cascade in  $U_3Si_2$  at 600 K.

given in Fig. 2 for the contribution of each defect to U and Si self-diffusion are as follows:

$$D_{V_U} = 1.113 \times 10^{-6} \cdot \exp\left(\frac{-2.900 \text{ eV}}{k_B T}\right) + 1.770 \times 10^{-46} \dot{F} \quad m^2 s^{-1} \quad (12)$$

$$D_{U_i} = 1.304 \times 10^{-6} \cdot \exp\left(\frac{-1.148 \text{ eV}}{k_B T}\right) \quad m^2 s^{-1} \quad (13)$$

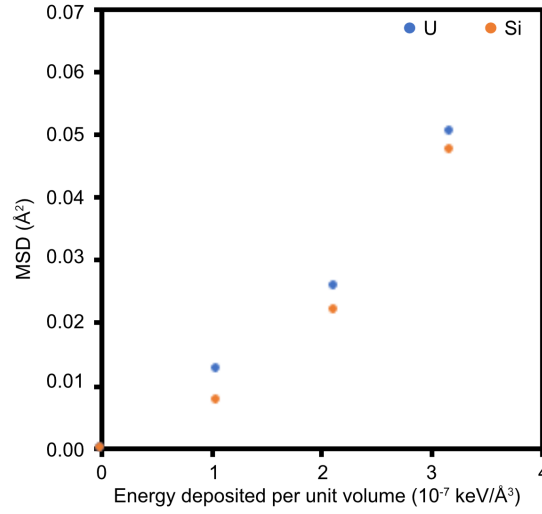

$$D_{V_{Si}} = 9.695 \times 10^{-4} \cdot \exp\left(\frac{-4.164 \text{ eV}}{k_B T}\right) + 1.971 \times 10^{-47} \dot{F} \quad m^2 s^{-1} \quad (14)$$

$$D_{Si_i} = 1.816 \times 10^{-5} \cdot \exp\left(\frac{-2.326 \text{ eV}}{k_B T}\right) \quad m^2 s^{-1} \quad (15)$$

where the first terms in all of the above equations represent thermal equilibrium  $D_1$  diffusion, while the second terms, if present, represent irradiation-enhanced  $D_2$  diffusion. These results are the contributions of the defects to self-diffusion and, as discussed later, this is different from the diffusivities used for Nabarro-Herring creep (where the rate limiting crystallographic direction is dominant).

### 3.1.2. Athermal $D_3$ diffusion

To simulate atomic mixing during the ballistic stopping of high energy fission fragments (responsible for athermal diffusion), damage cascade simulations were carried out. It was found that damage cascade simulations on this system required significantly smaller timesteps than usual. As such, PKA energies of 4 keV and above were not practical. PKA energies of 1 keV, 2 keV, and 3 keV were simulated, enabling the trend as a function of PKA energy to be identified. Figure 3 shows the MSD of Si and U in  $U_3Si_2$  as a function of time during a 3 keV ballistic cascade at 600 K. There was an initial rapid increase in atomic displacement that is maintained as atoms come to a rest some distance away from their initial positions.

**Figure 4:** The MSD of U (blue), and Si (orange) averaged over the final 15 ps of cascade simulations at 600 K as a function of the PKA energy deposited per unit volume. Each point is the average of 3 such cascade simulations.

Figure 4 shows the MSD of U and Si in  $\text{U}_3\text{Si}_2$  averaged over the final 15 ps of the simulation as a function of the PKA energy deposited per unit volume at 600 K. The data in Figure 4 has been averaged over 3 randomly orientated ballistic cascades for each PKA energy. The PKA energy deposited per unit volume is analogous to the heating density due to fission and will be used later to determine the athermal diffusion coefficient. It can be seen from Fig. 4 that greater displacement is predicted for U than Si. In previous work on  $\text{UO}_2$  [28], O displacement greatly exceeded that of U. It was speculated that the difference between U and O could be attributed either to the higher migration barriers and formation energies for U defects or to the much greater mass of U corresponding to lower velocities during mixing. However, in  $\text{U}_3\text{Si}_2$  displacement by ballistic cascades follows the same ordering as for the intrinsic diffusivities predicted by DFT ( $\text{U} > \text{Si}$ ) [29] and bears no correlation to the inverse of the atomic mass of the species ( $\text{Si} > \text{U}$ ). This supports the conclusion that in both systems the formation and mobility of the defects is more indicative of the extent of atomic mixing than is the mass of the species. However, it should be noted that for  $\text{U}_3\text{Si}_2$  the differences in the MSD of U and Si are small enough that it could be down to statistical variation or approximations inherent to the use of an empirical potential. Similar predictions were made by Beeler et al. [35] for athermal diffusion in UMo alloy, in that U and Mo have similar diffusivities.

The derivation of diffusivity from cascade simulations used here is analogous to that discussed previously [28, 35]. During fission a U atom splits into two high energy fission fragments characterized by a bi-modal distribution of the fission yield as a function of the fission fragment mass. On average the heavy fission fragment has 70 MeV of kinetic energy and the light fission fragment has 100 MeV. As the fission fragments travel through the lattice they experience drag (stopping) through interaction with the surrounding lattice. Initially traveling at high velocity, they interact most strongly with the electrons depositing 90 % of their initial energy electronically (based on the value for UC being representative of  $\text{U}_3\text{Si}_2$ , using the same assumption as in Ref. [36]). Due to the high thermal conductivity of  $\text{U}_3\text{Si}_2$  [15], it is assumed all energy that

**Table 4:** The  $\epsilon_B$ ,  $A_B$ , and  $D_3$  parameters for  $\text{U}_3\text{Si}_2$  from Eqs. (16) to (18).  $E_F$  is taken to be 170 MeV and it is assumed 10 % of this energy is deposited through ballistic stopping.  $D_3$  values assume a fission rate density of  $10^{19} \text{ m}^{-3}\text{s}^{-1}$ . These assumptions can be modified depending on reactor design or local irradiation conditions.

Species	$\epsilon_B \text{ (m}^5\text{MeV}^{-1}\text{)}$	$A_B \text{ (m}^5\text{)}$	$D_3 \text{ (m}^2\text{s}^{-1}\text{)}$
U	$1.46 \times 10^{-42}$	$4.15 \times 10^{-42}$	$4.15 \times 10^{-23}$
Si	$1.32 \times 10^{-42}$	$3.73 \times 10^{-42}$	$3.73 \times 10^{-23}$

has been deposited electronically dissipates before atomic mixing can occur through a thermal spike. Having slowed sufficiently, fission fragments deposit the remaining 10 % of their initial energy by interaction directly with the lattice through the creation of PKAs (as simulated here).

Typically diffusion occurs through thermal random walk, however, an equivalent diffusion coefficient,  $D_3$ , based on atomic mixing during irradiation can be determined:

$$D_3 = D_B + D_E \quad (16)$$

where  $D_B$  and  $D_E$  are the athermal diffusivity contributions from ballistic and electronic stopping, respectively. As discussed previously, electronic stopping is omitted ( $D_E = 0$ ) due to the high thermal conductivity exhibited by the metallically-bonded  $\text{U}_3\text{Si}_2$ . Therefore,

$$D_3 = A\dot{F} \quad (17)$$

$$A = \frac{0.1}{6} \epsilon_B E_F \quad (18)$$

where  $\dot{F}$  is the fission rate per unit volume, and  $A$  is the constant of proportionality between  $D$  and  $\dot{F}$ . The MSD per unit energy deposited in a unit volume of lattice during ballistic stopping is given by  $\epsilon_B$ , and is taken as the slope of a linear fit to the data in Fig. 4. The weighting factor of 0.1 is based on the proportion of fission energy,  $E_F$ , deposited ballistically rather than electronically, taken from Ref. [36].

Table 4 shows the values of  $\epsilon_B$  calculated at 600 K for U and Si. Note that we treat these values of  $\epsilon_B$  as valid for all temperatures, given that this mechanism was shown to be broadly athermal in  $\text{UO}_2$  and  $\text{UMo}$  [28, 35]. The parameter  $\epsilon_B$  can be considered as the efficiency of the mechanism in converting energy into atomic displacement. There is only marginal variation in  $\epsilon_B$  between U and Si. Table 4 shows  $\epsilon_B$ ,  $A$ , and  $D$  for U and Si. Our calculations of  $A$  and  $D$  are based on assumptions about the irradiation environment and radiation-material interactions. If one wishes to do so, different assumptions based on alternative irradiation environments (e.g. spent nuclear fuel storage conditions) can be used in conjunction with  $\epsilon_B$ . Alternatively, these parameters could be coupled with fuel performance simulations to give the local diffusivity based on the fission rate density in a specific part of the reactor or radial position in the pellet.

The contribution to self-diffusion from  $D_3$  is several orders of magnitude larger than the  $D_2$  diffusion terms calculated for  $V_{\text{Si}}$  and  $V_{\text{U}}$  in Eqs. (12) and (14). As such, in contrast to the behavior observed for  $\text{UO}_2$  [37], self-diffusion is dominated by  $D_1$  and  $D_3$  contributions only.

### 3.2. Diffusivity in the grain boundary

Self-diffusivity at grain boundaries is an important parameter that contributes to several phenomena that impact fuel performance, such as inter-granular bubble swelling. It is also the key parameter that governs the kinetics of Coble creep (as will be examined in more detail in Section 3.3.2). Following the procedure outlined in Section 2.2.3, a system containing two

$\Sigma$ -530 grain boundaries (in the  $x$ - $z$  plane) was equilibrated at various temperatures for 100 ps. Subsequently, the MSD in each direction orthogonal to the simulation cell was calculated for another 2 ns. In this section, we are interested in determining diffusivity specifically at the grain boundary itself. Therefore, we calculated the MSD for the perfect lattice at temperatures ranging from 1200 K to 1600 K, finding that no diffusion occurred on these timescales. As such, it can be assumed that all of the displacement that occurs in the grain boundary simulations is due only to displacement of atoms within the grain boundary. To convert the MSD for the entire supercell,  $\langle r^2 \rangle_{\text{supercell}}$ , into a grain boundary specific MSD,  $\langle r^2 \rangle_{GB}$ , a scaling factor based on the thickness of the grain boundary compared to the supercell length perpendicular to the grain boundary,  $L_Y$ , has been applied, as follows:

$$\langle r^2 \rangle_{GB} = \frac{L_Y}{4\delta} \langle r^2 \rangle_{\text{supercell}} \quad (19)$$

where  $\delta$  is the distance from the center of the grain boundary to the point where the lattice has bulk characteristics. The factor of 4 takes into account that this thickness applies to either side of the center of the grain boundary and that there are two grain boundaries in the supercell.  $\delta$  is taken to be 1 nm, however, as will be shown later, when calculating the Coble creep rate  $\delta$  is canceled out.

The derivative of  $\langle r^2 \rangle_{GB}$  with respect to time,  $t$ , was calculated by a linear fit to the MSD data from 1 ns to 2 ns. The diffusivity is given by:

$$D_{GB} = \frac{1}{2\xi} \frac{d \langle r^2 \rangle_{GB}}{dt} \quad (20)$$

where  $\xi$  is the dimensionality being considered when calculating  $D$ , such that  $\xi = 1$  for diffusivity in 1D (i.e.  $D_x$ ,  $D_y$ , and  $D_z$ ). Therefore, the diffusivity in the  $x$ - $z$  plane of the grain boundary,  $D_{GB\parallel}$ , is given by applying Eq. (20) to the 2D case, where  $\langle r^2 \rangle_{GB} = \langle x^2 \rangle_{GB} + \langle z^2 \rangle_{GB}$  and  $\xi = 2$ .

Figure 5 shows  $D_{GB\parallel}$  for U and Si in  $U_3Si_2$  as function of temperature. It can be seen that the grain boundary diffusivity of U is greater than that of Si. It is also noted that when the grain boundary was seeded with Si and U vacancies only a negligible change in the diffusivity was seen, consequently the impact of point defect concentration on grain boundary self-diffusion has been omitted from further analysis. For the purposes of developing a grain boundary (Coble) creep model for  $U_3Si_2$  fits to the data shown in Fig. 5 will be used. Arrhenius functions for U and Si grain boundary diffusion are, thus, given by:

$$U: \quad D_{GB\parallel} = 1.562 \times 10^{-6} \exp\left(-\frac{1.404 \text{ eV}}{k_B T}\right) \quad \text{m}^2 \text{s}^{-1} \quad (21)$$

$$Si: \quad D_{GB\parallel} = 6.411 \times 10^{-7} \exp\left(-\frac{1.619 \text{ eV}}{k_B T}\right) \quad \text{m}^2 \text{s}^{-1} \quad (22)$$

where these functions are also shown in Fig. 5 alongside the MD data. It is noted that there is some deviation from linearity in Fig. 5, which we attribute to the complex structure of the grain boundary. This results in many different migration pathways that, due to a range of activation energies, contribute to diffusion to a greater or less extent for different temperatures. In order to study this more carefully, MD simulations to lower temperatures would be necessary. However, insufficient displacement occurred below 1200 K on the ns-timescales used in this study.

**Figure 5:** The diffusivity of U ( $U_{GB}$ ) and Si ( $Si_{GB}$ ) at a  $\Sigma$ -530 tilt grain boundary,  $D_{GB\parallel}$ , predicted using molecular dynamics simulations. The fits to the MD data given by Eqs. (21) and (22).

### 3.3. Creep model

In this section we use the atomistic data for irradiation-enhanced bulk diffusion and grain boundary diffusion to derive correlations for creep mechanisms that are governed by point defect kinetics, namely: i) Nabarro-Herring creep, ii) Coble creep, and iii) dislocation climb.

#### 3.3.1. Nabarro-Herring creep

The defect concentrations calculated from the cluster dynamics simulations can be analyzed to understand thermal and irradiation-enhanced contributions to bulk diffusional creep (Nabarro-Herring creep). Nabarro-Herring creep is due to the diffusion of point defects under an elastic strain. The direction of the diffusion of a point defect is determined by the sign of the defect volume (change in lattice volume upon formation of the defect). Defects that contract (expand) the lattice are more favorably in regions of compressive (tensile) strain. Given that in  $U_3Si_2$  vacancies (interstitials) contract (expand) the lattice, the flow of mass is from the compressive to the tensile region of a grain (the defect volumes from Ref. [29] used here are summarized in Table 5). Therefore, bulk diffusion under a stress gradient enables plastic deformation (creep) that acts to relieve an applied stress.

The equivalent Nabarro-Herring creep rate,  $\dot{\epsilon}_{NH, x}$ , due to a given defect,  $x$ , is expressed as [38, 39]:

$$\dot{\epsilon}_{NH, x} = \frac{42|\Omega_x|D_x[x]}{k_B T d^2} \sigma_v \quad (23)$$

where  $\sigma_v$  is the Von-Mises stress, and  $d$  is the grain size.  $[x]$  and  $\Omega_x$  are the defect concentration (calculated in Section 3.1.1) and volume, respectively.  $D_x$  is the diffusivity of the defect. Due to the anisotropic nature of the  $U_3Si_2$  system,  $D_x$  must be selected carefully. Although more generally the defects will diffuse according to the specific tensile and compressive fields within the medium, for simplicity we have assumed that for Nabarro-Herring creep diffusion of point defects must occur from one side of the grain to a perpendicular (not opposite) side. This requires the defect to traverse both the  $aa$  and  $cc$  crystallographic directions. Diffusion in a single direction would not result in creep. Therefore, the slowest mobility direction will be

**Table 5:** Parameters describing defect diffusivities, from Andersson et al. [29], used in the Nabarro-Herring creep model. Migration barriers,  $H_{mig}$ , attempt frequencies,  $v_{mig}$ , dimensionality,  $\xi$ , jump distance,  $\alpha$ , number of jump sites,  $Z$ , and the defect volumes,  $\Omega_x$ , are reported.

Defect	$H_{mig}$ (eV)	$v_{mig}$ (Hz)	$\alpha$ (Å)	$\xi$	$Z$	$\Omega_x$ (Å <sup>3</sup> )
$U_i$	2.56	$1.00 \times 10^{14}$	3.90	1	2	0.07
$V_U$	1.71	$8.18 \times 10^{12}$	5.18	2	4	-4.17
$Si_i$	2.91	$1.00 \times 10^{13}$	3.90	1	8	4.09
$V_{Si}$	2.44	$1.00 \times 10^{13}$	4.19	1	2	-7.81

rate-limiting. As such, the defect diffusivities used for creep are different to those used to assess the defect concentrations during cluster dynamics simulations, and are given in Table 5.

Separate contributions from different defects to Nabarro-Herring creep were assessed using Eq. (23) with the defect concentrations from Section 3.1.1, resulting in the following expressions:

$$\dot{\epsilon}_{NH, V_U} = \frac{\sigma_v}{d^2 T} \cdot \left[ 1.457 \times 10^{-11} \cdot \exp\left(\frac{-3.400 \text{ eV}}{k_B T}\right) + 5.081 \times 10^{-51} \dot{F} \cdot \exp\left(\frac{-0.540 \text{ eV}}{k_B T}\right) \right] \quad (24)$$

$$\dot{\epsilon}_{NH, U_i} = \frac{\sigma_v}{d^2 T} \cdot 5.912 \times 10^{-14} \cdot \exp\left(\frac{-3.390 \text{ eV}}{k_B T}\right) \quad (25)$$

$$\dot{\epsilon}_{NH, V_{Si}} = \frac{\sigma_v}{d^2 T} \cdot \left[ 1.919 \times 10^{-8} \cdot \exp\left(\frac{-4.230 \text{ eV}}{k_B T}\right) + 5.958 \times 10^{-51} \dot{F} \cdot \exp\left(\frac{-0.090 \text{ eV}}{k_B T}\right) \right] \quad (26)$$

$$\dot{\epsilon}_{NH, Si_i} = \frac{\sigma_v}{d^2 T} \cdot 2.161 \times 10^{-10} \cdot \exp\left(\frac{-3.420 \text{ eV}}{k_B T}\right) \quad (27)$$

where  $\sigma_v$  is the Von-Mises stress in Pa,  $T$  is the temperature in K,  $d$  is the grain size in m,  $\dot{F}$  is the fission rate density in  $\text{m}^{-3}\text{s}^{-1}$ .

Figure 6 shows the Nabarro-Herring creep rate due to various defects assuming  $\dot{F} = 10^{19} \text{ m}^{-3}\text{s}^{-1}$  and  $\sigma = 50 \text{ MPa}$ . Given that the crystallographic direction with lower diffusivity is used for Nabarro-Herring creep, the interstitial contributions are greatly lowered with respect to that of the vacancies (as compared to their relative self-diffusivities, Fig. 2, which used the highest diffusivity direction). Note that only vacancy contributions have an irradiation-enhanced contribution, in line with the concentrations shown in Fig. 1. For both Si and U, the dominant mechanism at low temperatures is irradiation-enhanced vacancies. However, the irradiation-enhanced contribution is so low that it will result in negligible creep. At high temperatures, U vacancies and Si interstitials dominate.

The total Nabarro-Herring creep rate for a given species is given by the sum of the interstitial and vacancy contributions. However, for stoichiometric redistribution of material both U and Si must diffuse. Therefore, the rate limiting factor for all temperatures studied is U creep and the  $\text{U}_3\text{Si}_2$  Nabarro-Herring creep rate in  $\text{U}_3\text{Si}_2$  is given by:

$$\dot{\epsilon}_{NH} = \dot{\epsilon}_{NH, V_U} + \dot{\epsilon}_{NH, U_i} \quad (28)$$

### 3.3.2. Coble creep

The other contribution to diffusional creep is due to grain boundary diffusion (Coble creep). In Section 3.2, MD simulations were carried out to predict the grain boundary diffusivity of U

**Figure 6:** The Nabarro-Herring creep rate due to various point defects in  $U_3Si_2$  as described by Equations (24) to (27) with  $\sigma = 100$  MPa and  $\dot{\epsilon} = 10^{19} \text{ m}^{-3}\text{s}^{-1}$ .

and Si. The contribution to Coble creep for a given defect,  $x$ , is then given by [19]:

$$\dot{\epsilon}_{Coble, x} = \frac{42|\Omega_x|D_{GB}\pi\delta}{k_B T d^3} \sigma_v \quad (29)$$

where  $D_{GB\parallel}$  is given by Eqs. (21) and (22),  $\delta$  is the grain boundary thickness (assumed to 1 nm). Other parameters have the same definition as in Eq. (23). The resulting Coble creep rates for each defect are as follows:

$$\dot{\epsilon}_{Coble, V_U} = \frac{\sigma_v}{d^3 T} \cdot 6.228 \times 10^{-20} \cdot \exp\left(\frac{-1.404 \text{ eV}}{k_B T}\right) \quad (30)$$

$$\dot{\epsilon}_{Coble, U_i} = \frac{\sigma_v}{d^3 T} \cdot 1.046 \times 10^{-21} \cdot \exp\left(\frac{-1.404 \text{ eV}}{k_B T}\right) \quad (31)$$

$$\dot{\epsilon}_{Coble, V_{Si}} = \frac{\sigma_v}{d^3 T} \cdot 4.787 \times 10^{-20} \cdot \exp\left(\frac{-1.619 \text{ eV}}{k_B T}\right) \quad (32)$$

$$\dot{\epsilon}_{Coble, Si_i} = \frac{\sigma_v}{d^3 T} \cdot 2.507 \times 10^{-20} \cdot \exp\left(\frac{-1.619 \text{ eV}}{k_B T}\right) \quad (33)$$

Figure 7 shows the Coble creep rate for each defect as described by Eqs. (30) to (33). As before, the total creep rate for a given species is given by the sum of the vacancy and interstitial contributions. Unlike Nabarro-Herring creep, coble creep is rate limited by silicon defects due to their lower grain boundary diffusivity. Therefore, the  $U_3Si_2$  Coble creep rate is given as such:

$$\dot{\epsilon}_{Coble} = \dot{\epsilon}_{Coble, V_{Si}} + \dot{\epsilon}_{Coble, Si_i} \quad (34)$$

### 3.3.3. Dislocation climb

The arrival of vacancies at dislocations controls the rate at which they are able to climb over obstacles, freeing them and enabling them to glide. Therefore, the creep rate due to dislocation climb can be written in terms of the vacancy diffusivity,  $D_v$ , as follows [40]:

$$\dot{\epsilon}_{Climb} = A_1 \frac{D_v[x]\mu b}{k_B T} \left(\frac{\sigma_v}{\mu}\right)^3 \quad (35)$$

**Figure 7:** The Coble creep rate due to various point defects in  $U_3Si_2$  as described by Eqs. (30) to (33) with  $\sigma = 100$  MPa.

where  $\mu$  is the shear modulus (taken as 50 GPa from Ref. [41]),  $b$  is the burgers vector (estimated here as the average lattice parameter of  $U_3Si_2$ , 5.6 Å), and  $A_1$  is a dimensionless constant of proportionality of the order of unity (taken in this work to be exactly 1). Equation (35) represents the simplest form of the climb equation and it is not uncommon that in practice the exponent for stress will exceed 3. Due to limited data available to validate our  $U_3Si_2$  models we have selected to leave the power law exponent as 3. Future work should revisit this as more data becomes available and the underlying models become more sophisticated. The ability of a vacancy to activate the climb mechanism is independent of the crystallographic direction it arrives along, therefore  $D_v$  is based on the higher mobility lattice direction (as described by the parameters in Table 2). As for Nabarro-Herring creep the defect concentrations,  $[x]$ , are taken from the cluster dynamics simulations and, therefore, account for irradiation effects. The slowest of  $V_{Si}$  or  $V_U$  was taken to be the rate limiting defect. The correlation for the creep rate due to dislocation climb is, thus, given by:

$$\dot{\epsilon}_{Climb} = \frac{\sigma^3}{T} \cdot \left( 1.512 \times 10^{-11} \cdot \exp\left(\frac{-4.160 \text{ eV}}{k_B T}\right) + 4.696 \times 10^{-55} \dot{\epsilon} \cdot \exp\left(\frac{0.020 \text{ eV}}{k_B T}\right) \right) \quad (36)$$

### 3.3.4. Validation of creep model

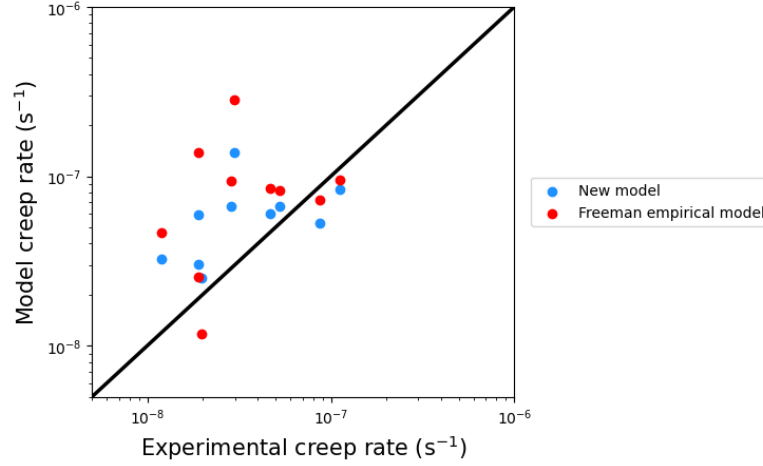

To test the accuracy of our model, validation has been carried out against literature compression creep tests [41]. Figure 8 shows an Ashby plot where the color indicates the relative contribution of Nabarro-Herring (red), Coble (green), and climb (blue) creep at a given stress and temperature. As expected, Coble creep dominates at low temperatures and low stresses, while dislocation climb dominates for high temperature and high stresses. Nabarro-Herring creep makes only a small contribution at temperatures near the melting point.

The conditions at which the experimental data from Ref. [41] were measured are shown by white data points in Fig. 8. Table 6 shows the same conditions alongside the measured creep rates and the values predicted by our model (assuming a grain size of 20  $\mu m$ ). All of our model predictions are within one order of magnitude of the experimental data, with an average error of  $\pm 38\%$ . Given the exponential nature of an Arrhenius relationship and that no experimental data was used to derive our model, this represents reasonable agreement. Additionally, there is a degree of uncertainty within the experiments that prevents perfect agreement.

**Figure 8:** An Ashby diagram illustrating the relative contribution of Nabarro-Herring (red), Coble (green), and climb (blue) creep at a given stress and temperature ( $\dot{\epsilon} = 10^{19} \text{ m}^{-3}\text{s}^{-1}$ ). The white data points indicate the conditions at which literature experiments [41] had been carried out.

**Figure 9:** A parity plot comparing the modeled creep rate against the results from compressive creep tests [41]. The new model presented here is shown alongside the empirical model from Freeman [20]. The solid line indicates perfect agreement between the experiment and the model.

Figure 9 is a parity plot comparing the model predictions ( $y$ -axis) with the experimental data ( $x$ -axis). The results using the new model presented in this report are shown in blue alongside the empirical model developed by Freeman [20] in red. The closer the points are to the solid black line the better the agreement between experiment and modeling. Our model predicts slightly lower creep than the empirical correlation of Freeman et al. [20]. Figure 9 shows that application of the DFT and cluster dynamics data for point defect diffusivity provides a slight improvement on the empirical Freeman model [20, 42] that was derived from a subset of the experimental data shown in Table 6. Additionally, the new model has the benefit of including the dependence of creep rate on grain size and fission rate density, which enables coupling to a grain growth model for  $\text{U}_3\text{Si}_2$  or to variations in the linear heating rate, respectively. Note

**Table 6:** Comparison of the model against creep tests on  $\text{U}_3\text{Si}_2$  [41]. Experimental temperatures ( $T$ ), stresses ( $\sigma$ ), and strain rates ( $\dot{\epsilon}_{Expt.}$ ) are provided in Ref. [41]. The strain rates from our model ( $\dot{\epsilon}_{Model}$ ) are also reported for the same conditions.

Creep test	$\sigma$ (MPa)	$T$ (K)	$\dot{\epsilon}_{Expt.}$ ( $\text{s}^{-1}$ )	$\dot{\epsilon}_{Model}$ ( $\text{s}^{-1}$ )
1	44.10	1218.37	$8.7327 \times 10^{-8}$	$5.3136 \times 10^{-8}$
2	71.77	1205.18	$1.1134 \times 10^{-7}$	$8.3291 \times 10^{-8}$
4	77.68	1122.24	$1.9769 \times 10^{-8}$	$2.5066 \times 10^{-8}$
5	57.69	1210.10	$5.2848 \times 10^{-8}$	$6.6500 \times 10^{-8}$
6	46.81	1173.58	$1.9071 \times 10^{-8}$	$3.0276 \times 10^{-8}$
7	45.65	1223.59	$4.6836 \times 10^{-8}$	$5.9858 \times 10^{-8}$
9	49.43	1223.56	$2.8543 \times 10^{-8}$	$6.6393 \times 10^{-8}$
11	27.36	1223.70	$1.1998 \times 10^{-8}$	$3.2613 \times 10^{-8}$
12	26.40	1273.60	$1.8869 \times 10^{-8}$	$5.9577 \times 10^{-8}$
13	47.77	1273.61	$2.9740 \times 10^{-8}$	$1.3883 \times 10^{-7}$

that the impact of varying grain size on diffusivity, which would in turn influence the creep rate beyond the correlation shown in Eqs. (23) and (29), has not been included. However, given that the irradiation-enhanced creep rates are so low in our model, this will not influence the in-reactor behavior of  $\text{U}_3\text{Si}_2$ . We also note that validation of our model would benefit from additional experimental data than spans a larger range of conditions.

#### 3.4. Implementation of creep model in BISON

The description of creep in  $\text{U}_3\text{Si}_2$ , given by the sum of the Nabarro-Herring (see Eq. (28)), Coble (see Eq. (34)), and climb (see Eq. (36)) contributions, has been implemented into the BISON fuel performance code to demonstrate the application of the lower length scale (LLS) informed creep model for engineering scale simulations.

Due to the very high thermal conductivity of  $\text{U}_3\text{Si}_2$  [15] the temperatures are low, compared to  $\text{UO}_2$ , for typical LWR operating conditions (e.g., linear powers of 20-25 kW/m). Furthermore, the irradiation-enhanced terms (proportional to  $\dot{F}$ ) are also very small. As such, for normal LWR linear powers virtually no creep is observed. Therefore, in order to test the model for higher temperatures a steady-state linear power of 35 kW/m, which might occur in a test reactor, was also examined and held for  $\sim 3.2$  years. Figure 10 presents a) the predicted fuel outer diameter at the end of the simulation as well as b) the time history of the fuel centerline temperature during the simulation. One observes that the end-of-life diameter is slightly larger ( $< 0.01$  mm) in the case with creep indicating that by computing creep there is an observable, but insignificant effect on the final fuel diameter. Similarly, the larger fuel diameter results in a marginally lower average centerline temperature due to a reduced pellet-clad gap, which increases the gap conductance.

To examine the possibility that a temperature transient due to a LOCA might cause higher creep rates, an increasing temperature on the outer cladding surface was prescribed, as shown in Fig. 11. This temperature corresponds to the maximum prescribed temperature and a sinusoidal profile is applied such that the temperature is 20 K less at the rodlet ends. Figure 12 shows the distribution of the creep strain (radial, axial, and hoop directions) throughout the pellet at the end of the LOCA simulation. It can be seen that the strain is still limited despite the higher temperature induced by the LOCA. This is due to the failure of the cladding at 1100 K, as a result of ballooning. At such temperatures, the creep model derived in this work still results in low creep rates. Following the failure of the cladding, the temperature continues

**Figure 10:** The (a) end-of-life diameter of the fuel and (b) the time history of the average centerline temperature.

to increase up to 1400 K where significant creep rates might be expected. However, following failure of the cladding the stress imparted by the cladding and rod internal pressure on the pellets has been eliminated, thus, removing the driving force for creep. Under a station blackout scenario, whereby the pressure on the fuel remains as the temperatures rise, the creep of  $U_3Si_2$  might become more significant for fuel performance.

**Figure 11:** The cladding temperature prescribed during the LOCA transient.

**Figure 12:** The creep strain in (a) radial, (b) axial, and (c) hoop directions within the fuel at the time of cladding failure during the transient

#### 4. Conclusions

$\text{U}_3\text{Si}_2$  is considered as an advanced nuclear fuel candidate due to its high thermal conductivity and high uranium density. These properties are beneficial for the performance and economics of nuclear fuel. However, due to the lack of experience of using  $\text{U}_3\text{Si}_2$  as a nuclear fuel there is limited data for the thermophysical and thermomechanical properties that are required to build fuel performance modeling capability. In this work, we employ atomic scale simulations of point defect self-diffusion under irradiation to derive a creep model for  $\text{U}_3\text{Si}_2$ .

Atomic scale modeling in combination with cluster dynamics simulations have been used to examine self-diffusion in  $\text{U}_3\text{Si}_2$ . It was found that thermal equilibrium diffusion ( $D_1$ ) and athermal atomic mixing due to ballistic cascades ( $D_3$ ) dominate self-diffusion, whereas irradiation-enhanced diffusion ( $D_2$ ) did not contribute significantly. In addition to irradiation-enhanced bulk diffusion (described by  $D_1$ ,  $D_2$ , and  $D_3$ ), grain boundary diffusivity (in-plane),  $D_{GB\parallel}$ , was simulated using MD, finding that U has higher  $D_{GB\parallel}$  than Si.

Based on the thermal equilibrium ( $D_1$ ) and the irradiation-enhanced ( $D_2$ ) defect concentrations and their mobilities in bulk  $\text{U}_3\text{Si}_2$ , models for Nabarro-Herring creep and dislocation climb were derived. Similarly, a Coble creep model was developed using the MD simulation results for grain boundary diffusion. The combined creep model captures the impact of fission rate, stress, and grain size on creep rate. The new creep model compared reasonably with the available experimental data and has been implemented in the fuel performance code BISON. The model was tested for both steady-state and LOCA conditions, finding that limited creep occurred. As more experimental data for  $\text{U}_3\text{Si}_2$  creep becomes available the model should be further validate to confirm this finding.

#### Acknowledgments

Funding for this work was provided by the US Department of Energy, Office of Nuclear Energy NEAMS (Nuclear Energy Advanced Modeling and Simulation) and CASL (Consortium for Advanced Simulation of Light Water Reactors) programs. Los Alamos National Laboratory, an affirmative action/equal opportunity employer, is operated by Triad National Security, LLC, for the National Nuclear Security Administration of the U.S. Department of Energy under Contract No. 89233218CNA000001.
