## Abstract

A U-Mo alloy has been selected as the fuel design for the conversion of high-performance research reactors in the United States. Efforts are ongoing to describe the fuel evolution as a function of time, for a variety of different reactor conditions. The accurate prediction of fuel evolution under irradiation requires the implementation of correct thermodynamic properties into mesoscale and continuum-level fuel performance modeling codes. Molecular dynamics has proven to be a valuable tool to parameterize or inform these higher-length scale models. However, there are currently inaccuracies in the only available U-Mo-Xe potential, which limits the predictive capabilities of molecular dynamics to inform critical phenomena in these fuel systems such as fission gas swelling. This work provides an updated U-Mo-Xe ternary interatomic potential which combines existing potentials in a reconciled format. The validation of the interatomic potential is performed by analyzing the phase stability and vacancy formation energies. Subsequently, Xe solution energies and an equation of state to describe Xe bubbles in U-Mo are calculated, providing 1) evidence of the significant differences between the prior ternary potential and the currently presented potential, and 2) updated data/tools for implementation into mesoscale simulation methodologies to study fission gas bubble evolution.

---

## 1. Introduction

The United States High-Performance Research Reactor (USHPRR) program plans to replace current highly enriched uranium (HEU) fuel in high-power research reactors with low enriched uranium (LEU) fuel [1]. In order to achieve a reduced enrichment in these fuel types while maintaining the power density, there is 5 a requirement for increased uranium density. The design for conversion includes a monolithic foil of uranium with 10 wt% molybdenum, with a zirconium diffusion barrier in aluminum cladding.

Recently, substantial effort has been made on mesoscale models to predict the swelling behavior of U-Mo fuels [2, 3, 4, 5, 6, 7, 8, 9]. These models rely on phase-field and/or rate theory descriptions of the microstructure evolution of material systems in order to model swelling on realistic timescales. These

10 simulation methodologies include a number of parameters that are either fit to limited experimental data, calculated from lower length scale modeling methodologies, or assumed based on other material systems. Classical molecular dynamics (CMD) have proven valuable for the parametrization of such mesoscale models [10, 11, 12, 13, 14]. However, there are specific limitations to the present interatomic potentials (which are required for CMD simulations) that inhibit the scope of research that is currently capable.

15 The two interatomic potentials that have been used for the majority of the cited research are from Smirnova [15] and Starikov [16]. The Smirnova potential is an embedded-atom method (EAM) [17, 18] interatomic potential that includes descriptions for U, Mo, and Xe. At the time of its development, to the authors' knowledge, it was the only potential capable of describing any of the pair systems included in this ternary. Thus, it presented a dramatic advancement in terms of available tools for the exploration of the  
20 U-Mo system. In particular, the inclusion of Xe in this potential allowed for the analysis of gas bubble behavior, which is a critical phenomenon related to the performance of U-Mo fuels [19, 20]. However, certain properties of the  $\gamma$  phase of U-Mo were found to not be well captured by this EAM potential, such as point defect diffusion coefficients and phase stabilities [15, 16]. In particular, as will be shown later, the body-centered-cubic (bcc) solid solution phase was found unstable with Mo precipitate formation in the U matrix.  
25 In the literature, efforts have been put forth by Starikov et al. [16] to improve upon the EAM potential and develop a U-Mo potential in the angular dependent potential (ADP) formalism [21]. The ADP-type potential can correctly predict the stability of the bcc solid solution phase of U-Mo. Although there is a dramatically improved performance of the ADP compared with the EAM potential, the interactions for Xe were excluded in the ADP parametrization, and this limits the applicability of the ADP-type potential for  
30 Xe in U-Mo.

Motivated by the need of simulating Xe with a reliable potential for U-Mo, this work bridges prior separated Xe-U, Xe-Mo, and Xe-U-Mo interactions, with the U-Mo ADP developed by Starikov et al. [16] to achieve an interatomic potential for the U-Mo-Xe system. The interatomic potential is validated, and prior results investigating the U-Mo-Xe system are investigated to demonstrate the differences from prior ternary  
35 descriptions.

## 2. Computational Details

### 2.1. Background

The ADP [21] formalism is a generalization of the EAM type potential, where the total energy  $E_i$  of an atom  $i$  is given by:

$$E_i = F_\alpha \left( \sum_{j \neq i} \rho_\beta(r_{ij}) \right) + \frac{1}{2} \sum_{j \neq i} \phi_{\alpha\beta}(r_{ij}) + \frac{1}{2} \sum_s (\mu_i^s)^2 + \frac{1}{2} \sum_{s,t} (\lambda_i^{st})^2 - \frac{1}{6} \nu_i^2 \quad (1)$$

$$\mu_i^s = \sum_{j \neq i} u_{\alpha\beta}(r_{ij}) r_{ij}^s \quad (2)$$

$$\lambda_i^{st} = \sum_{j \neq i} w_{\alpha\beta}(r_{ij}) r_{ij}^s r_{ij}^t \quad (3)$$

$$\nu_i = \sum_s \lambda_i^{ss} \quad (4)$$

where  $F$  is the embedding energy and is a function of the electron density ( $\rho$ ),  $\phi$  is a pair potential interaction,  $\alpha$  and  $\beta$  are the element types of atoms  $i$  and  $j$ , and  $s$  and  $t = 1, 2, 3$  and refer to the Cartesian coordinates.

45 The  $\mu$  and  $\lambda$  terms represent the dipole and quadrupole distortions of the local atomic environment. This formalism extends the original EAM (the first two terms in eq. (1)) by introducing angular forces as dipole and quadrupole moments (third, fourth, and fifth terms). A similar approach that involves the modification of the EAM formalism to include angular forces is the modified-EAM (MEAM) [22, 23].

A given ternary potential requires interactions for each of the three species themselves, and interactions 50 between each species, for a total of six pair descriptions. The U-U, Mo-Mo, and U-Mo interactions are taken from the 2018 version of the Starikov U-Mo ADP [16]. The descriptions of U-Xe, Mo-Xe, and Xe-Xe interactions have been previously parameterized, but for an EAM interatomic potential [15]. Thanks to the shared underlying physics between the EAM and the ADP-type interatomic potentials, the EAM-based Xe pair interactions can be implemented into an ADP formalism, provided that appropriate scaling is 55 performed. Therefore, the construction of a ternary interatomic potential in this work should not necessarily be considered a development step, but a reconciliation step, where multiple models have been unified under a single potential formalism, but the underlying descriptions have remained unchanged.

## 2.2. Potential Adjustment

This work makes use of the assumption that for Xe interactions no angular forces are required for the 60 accurate representation of forces. Given the noble nature of Xe interactions and the lack of unpaired valence electrons, we believe that this is a reasonable assumption. Therefore, the EAM descriptions from Smirnova [15] can be taken as complete, and the third, fourth, and fifth terms in eq. (1) can be set to zero.

The first step in the reconciliation procedure involves an invariant scaling process. The quantity  $\bar{\rho}$  is given by the sum:

$$\bar{\rho} = \sum_{j \neq i} \rho(r_{ij}) \quad (5)$$

65 where  $\rho$  is the electron density. The energy and forces in the system are invariant to the scaling of the electron density and the embedding energy,

$$\rho(r_{ij}) = \alpha \rho(r_{ij}) \quad (6)$$

$$F(\bar{\rho}) = F\left(\frac{\bar{\rho}}{\alpha}\right) \quad (7)$$

where  $F$  is the embedding energy and  $\alpha$  is a scale factor. This scaling does not change the properties of the pure systems but does in fact change the behavior of the multi-component system. The scale factor was applied only to Xe, and in such a fashion as to lead to the same electron density range as that employed  
70 for the U-Mo ADP. No further scaling is required, as the distance range and discretization are identical for both the ADP and EAM potentials utilized.

### 2.3. Molecular Dynamics Simulations

Simulations were performed utilizing the LAMMPS [24] software package and the U-Mo-Xe potential constructed in this work. General simulation details are listed here, and further information, where necessary,  
75 is included in the results section.

#### 2.3.1. Phase stability

The stability of the bcc  $\gamma$  phase was examined by calculating the  $c/a$  ratio as a function of temperature and Mo molar fraction,  $c_{Mo}$ , and the stability of the bcc U-10Mo solid solution against phase separation.

A bi-crystal simulation cell with a  $\langle 100 \rangle \Sigma 5$  symmetrical tilt grain boundary was used to study possible  
80 phase separation and grain boundary segregation. The simulation cell was 15.2 nm (x) by 1.4 nm (y) by 30.4 nm (z) in size and contained 21.6 atomic percent Mo for the purpose of representing U-10Mo. The grain boundary was inserted in the x-y plane. After the relaxation of the initial simulation cell, hybrid molecular dynamics / Monte Carlo (MDMC) simulations were carried out at 300, 600, and 900 K. Both the EAM and ADP-type potentials have been utilized to compare their performance. In the MDMC simulations, a  
85 randomly selected Mo atom was swapped with a randomly selected U atom at every MD step. The change in total potential energy,  $\Delta E$ , was calculated. The swap was accepted if  $\xi < \exp(-\frac{\Delta E}{K_B T})$  and rejected otherwise. Here  $K_B$  is the Boltzmann constant, and  $\xi$  is a random number in the range of 0 to 1. Each simulation lasted until the total potential energy converged.

To compute the  $c/a$  ratio, a  $20 \times 20 \times 20$  bcc simulation cell was used with 16000 atoms. The Mo molar  
90 fraction was varied from 0 to 1, with an incremental step of 0.1. The point  $c_{Mo} = 0.216$  was also inserted to represent U-10Mo. The temperature was varied from 0 to 1000 K, with one data point every 100 K. At each temperature and for each Mo fraction, the length of the cell along the three principal axes was relaxed using a zero-stress boundary condition. The cells were found to evolve into either a body-centered-tetragonal (bct) or bcc structure, i.e., the  $\gamma$  phase. Here,  $c$  is taken as the smallest lattice parameter in an orthorhombic  
95 unit cell and  $a$  as the average of the two other lattice parameters. The  $\gamma$  phase is indicated by  $c/a \approx 1$ , while  $c/a < 1$  represents the bct phase. It should be noted that at high temperatures,  $c/a$  is not exactly 1 because of thermal fluctuations in the simulations, and we took  $c/a > 0.99$  as the criteria for the appearance of the  $\gamma$  phase.

### 2.3.2. Vacancy formation energy and Xe solution energy

100 The vacancy formation energy,  $E_v^f$ , and Xe solution energy,  $E_{Xe}^s$ , were also computed at 300 K as a further test of the potential. The vacancy formation energy is defined as

$$E_v^f = E(N_U N_{Mo} V_1) - N_U \mu_U - N_{Mo} \mu_{Mo} \quad (8)$$

The Xe solution energy is defined as

$$E_{Xe}^s = E(N_U N_{Mo} Xe_1) - N_U \mu_U - N_{Mo} \mu_{Mo} - \mu_{Xe} \quad (9)$$

In the above equations,  $E(N_U N_{Mo} V_1)$  is the total energy of simulation cells with  $N_U$  U atoms,  $N_{Mo}$  Mo atoms, and one vacancy, and  $E(N_U N_{Mo} Xe_1)$  is the corresponding total energy when the vacancy is occupied by a Xe atom, forming a Xe substitutional.  $\mu_U$  and  $\mu_{Mo}$  are the chemical potentials of U and Mo, respectively. The calculations were performed using a  $10 \times 10 \times 10$  cell with 1568 U and 432 Mo atoms, representing U-10Mo. An NPT (constant pressure and constant temperature) ensemble with zero external pressure and a temperature at 300 K was used for the calculation. A random atom was either removed or replaced with Xe to create a vacancy or Xe substitutional. The statistical approach recently proposed [25] was used to compute  $E_v^f$ ,  $\mu_U$ , and  $\mu_{Mo}$ , which were then used to compute  $E_{Xe}^s$  using eq.9.

### 2.3.3. Xe Bubble Equation of State

A supercell of 40x40x40 bcc unit cells (128,000 U atoms) was generated, and 21.6 percent of U atoms are randomly switched to Mo atoms, yielding a U-10Mo alloy in the bcc structure. Relaxation of the bulk system was performed in an NPT ensemble, relaxing each x, y, and z component individually, with a damping parameter of 0.1 ps. Temperatures of interest were 300 - 700 K, in increments of 100 K, which spans the realistic operating temperatures for U-Mo fuels [26]. The system was allowed to equilibrate for 200 ps at a given temperature, and subsequently, a void was constructed by deleting a sphere of atoms from the center of the supercell. This void was relaxed for 200 ps under the same simulation conditions described above. Different sizes of voids are prescribed to ensure that there were no simulation artifacts present due to the existence of a single bubble size. Voids were ensured to be sufficiently large that the surface energy had converged [14].

In order to analyze bubbles, simulations were performed in an NVT ensemble to mimic a bubble in a very large system that effectively exerts a resistive pressure on the bubble. This allows for the calculation of a Xe bubble pressure and a subsequent equation of state (EOS) based on the density of the bubble. The generation of bubbles was performed by inserting Xe atoms into the void one at a time, while the relaxation of the system is ongoing. The insertion rate was less than one Xe atom per 8 ps for all systems. The rate of insertion was modified according to the bubble size in order to ensure a similar rate of Xe to vacancy ratio change as a function of time. In order to track the bubble size, two atoms (one on either side of the void) were tracked throughout the simulation and the distance between the two atoms is classified as the diameter of the bubble. The pressure of the bubble was determined by computing the stress per atom on each of the

Xe atoms in the system, summing the individual components of the stress tensor over all Xe atoms, and finally dividing by the degrees of freedom (three) and the volume of the bubble.

A minimization script was utilized to fit the EOS for a Virial functional form to the determined pressure and molar volume data from the molecular dynamics simulations. The data was input into the script, and  
135 the relative error was summed and utilized to optimize the EOS, iterating by providing a random step to each of the fitting coefficients and only accepting the iteration if the total relative error is reduced. This methodology is in accordance with a prior study [14] developing a Xe bubble EOS utilizing the U-Mo-Xe EAM potential.

### 3. Results

#### 140 3.1. Interatomic potential validation

##### 3.1.1. Phase stabilities and structural constants

The MDMC simulations with the EAM and ADP-type potentials predicted different stabilities for the bcc solid solution phases. As shown in figure 1(a), with the EAM potential, U-10 Mo solid solution was not stable and went through a phase separation with the formation of Mo precipitates. The same results  
145 were obtained at all three simulation temperatures, 300 K, 600 K, and 900 K. In contrast, no such phase separation was observed in the simulations with the ADP-type potential at all three temperatures, where the solid solution U-10Mo remained stable, as shown in figure 1(b). This again indicates the benefit of achieving an ADP-type potential with Xe. In all simulations with both potentials, no substantial grain boundary segregation was identified.

150 The stable zone of the  $\gamma$  phase is shown by the c/a ratio plotted in figure 2. The bct phase is stable when  $T < 650$  K and the molar fraction of Mo  $c_{Mo} < 0.2$ . In this zone, the c/a ratio increases with increasing  $c_{Mo}$  and is insensitive to temperature with a weak U-shaped dependence. In contrast, the  $\gamma$  phase, indicated by  $c/a \approx 1$ , is stable when  $T > 650$  K or  $c_{Mo} \geq 0.2$ . Although the bct phase is not exactly the same as the  $\alpha$ -U structure, and the transition temperature is lower than the actual  $\alpha - \beta$  transition point of U,  
155 figure 2 indicates that the potential captures the overall behavior that the  $\gamma$  phase is stabilized by increasing temperature and Mo concentration. It is thereby applicable for studying the properties of U-Mo systems either with high Mo content or at high temperatures.

#### 3.2. Xe substitution in U-Mo

The vacancy formation energy  $E_v^f$  and the Xe solution energy  $E_{Xe}^s$  are shown in figure 3, both exhibiting  
160 a probability distribution, indicating the dependence on local atomic environment. Such a dependence is typical in concentrated alloys and implies the importance of sampling different atomic environments. The distributions were fitted using the Gaussian distribution function based on their shapes. The mean and standard deviations obtained from the fitting are listed in Table 1 along with the chemical potentials of U and Mo as well. The mean vacancy formation energy  $\langle E_v^f \rangle$  computed is 1.67 eV. This value is higher than

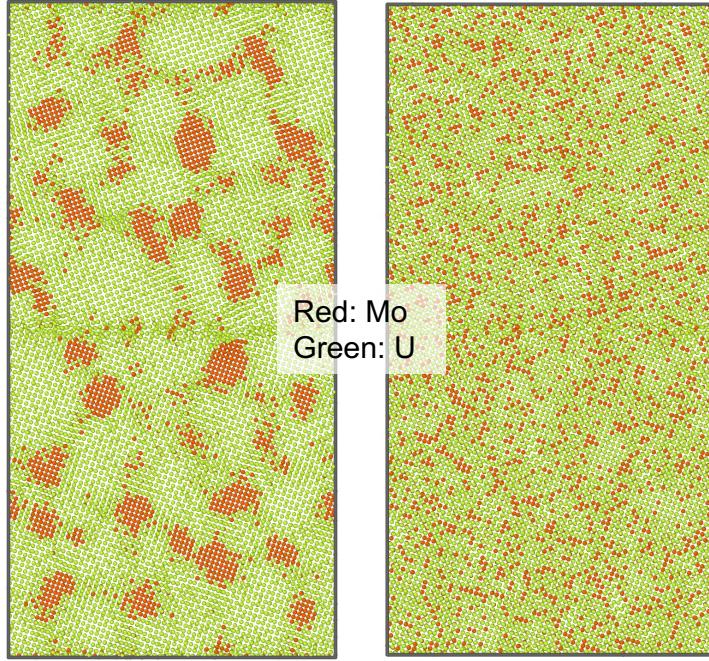

Figure 1: Atomic configurations from hydrid MDMC simulations at 900 K showing (a) Mo precipitation with the EAM potential and (B) stable solid solution with the ADP-type potential.

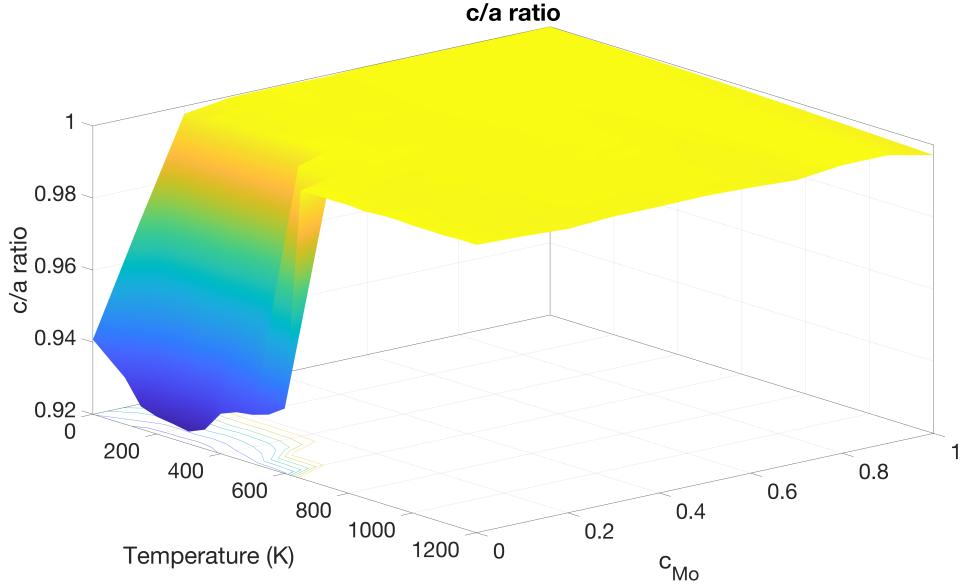

Figure 2: The c/a ratio as a function of Mo molar fraction and temperature.

the average value obtained by Jin et al. in U-20Mo (in atomic percent) at 0 K using the same ADP-type potential [27], where the formation energies for U-vacancy (vacancy created by removing a U atom) and Mo-vacancy were computed to be 1.07 eV and 1.30 eV, respectively. The discrepancy may come from the different methods used for deriving the chemical potentials. In Jin et al., the potential per atom averaged

over all atoms was used for the chemical potential for both U and Mo, and in this work, the chemical potentials and U and Mo were derived separately with a notable difference, as given in Table 1. The mean Xe solution energy is 10.29 eV, much higher than that calculated using the EAM potential, 6.1 eV [14].

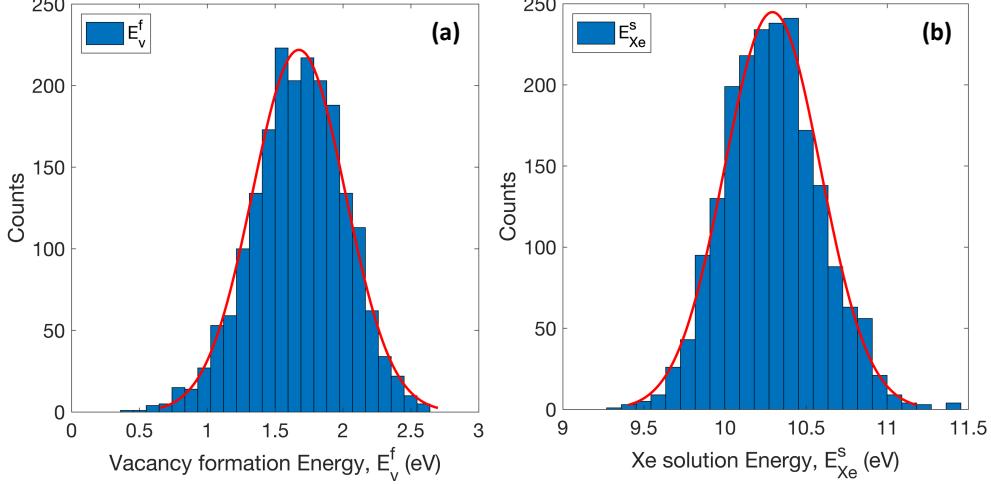

Figure 3: Distributions of (a) vacancy formation energy and (b) Xe solution energy in U-10Mo.

Quantity	$\mu_U$	$\mu_{Mo}$	$\langle E_v^f \rangle$	$\langle \sigma_v^f \rangle$	$\langle E_{Xe}^s \rangle$	$\langle \sigma_{Xe}^s \rangle$
Value	-4.1125	-6.6934	1.6748	0.3415	10.2924	0.2965

Table 1: Chemical potentials of U and Mo,  $\mu_U$  and  $\mu_{Mo}$ , mean vacancy formation energy  $\langle E_v^f \rangle$ , and the standard deviation  $\langle \sigma_v^f \rangle$ , mean Xe solution energy,  $\langle E_{Xe}^s \rangle$ , and the standard deviation,  $\langle \sigma_{Xe}^s \rangle$ , in U-10Mo calculated at 300 K using molecular dynamics simulations, all in units of eV.

The Xe solution energy is plotted against the numbers of 1<sup>st</sup> nearest neighbor (1NN) and 2NN Mo atoms in figure 4. It is found to increase with the number 1NN Mo atoms, suggesting that Xe prefers a U-rich environment. No clear dependence on the number of 2NN Mo atoms can be identified, indicating that the dependence is very local within the 1NN distance.

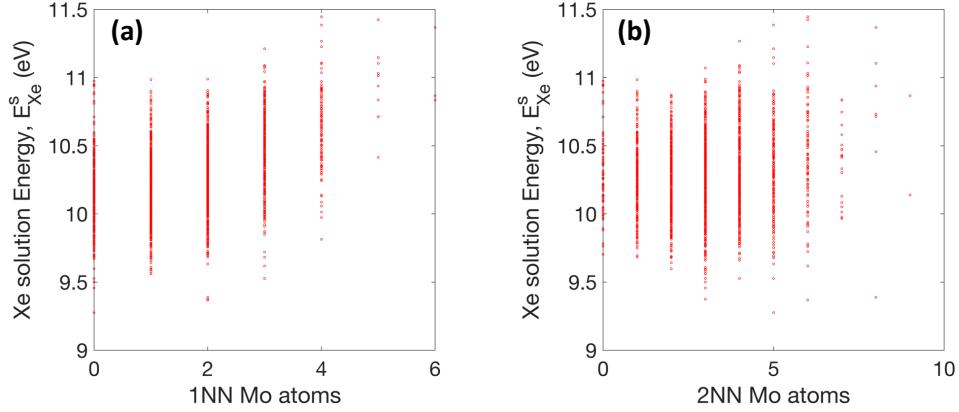

Figure 4: Dependence of Xe solution energy on the number of (a) 1<sup>st</sup> nearest neighbor (1NN) and (b) 2NN Mo atoms.

### 3.2.1. Voids and bubbles in U-Mo

### 3.3. Surface energies of voids

In order to generate bubbles, voids of varying size must be generated. This allows for the calculation of a void surface area as a function of radius, and the surface energy can be determined from equation 10

$$E_{surf} = \frac{(E^* - E)}{A} \times N \quad (10)$$

where  $E^*$  is the potential energy per atom of the system with a void,  $E$  is the potential energy per atom of the perfect crystal of U-Mo,  $A$  is the total surface area of the void, and  $N$  is the number of atoms in the system with a void. The void surface energy is shown in Fig. 5 as a function of the void radius.

It can be observed that the void surface energy converges above a radius of 1.5 nm for all temperatures to a value of approximately 1.5 J/m<sup>2</sup>. Also, the void surface energy tends to increase slightly with increasing temperature. This is in accordance with the average surface energy for U-Mo planar surfaces as determined in [28], which utilized the Starikov ADP [16]. It should be noted that the EAM potential was previously utilized to analyze void surface energy, and predicted a value 0.4 J/m<sup>2</sup> lower than the value reported here. This provides confidence in the accurate implementation of the potential, validation of different methodologies for obtaining average surface energies, and underlines the importance of this work to incorporate a more accurate U-Mo potential which can also describe Xe interactions.

### 3.4. Xe bubble equation of state in U-Mo

The equation of state (EOS) can be determined by tracking the pressure inside the bubble and the bubble size as a function of the number of Xe atoms present in the bubble while the system is equilibrated in an NVT ensemble, which provides a pressure versus density relationship. This data can be fit to an EOS that provides a generalized function predicting the relationship between pressure, temperature, and molar volume. In order to extend the applicability of the EOS, temperatures from 300 K to 700 K are analyzed,

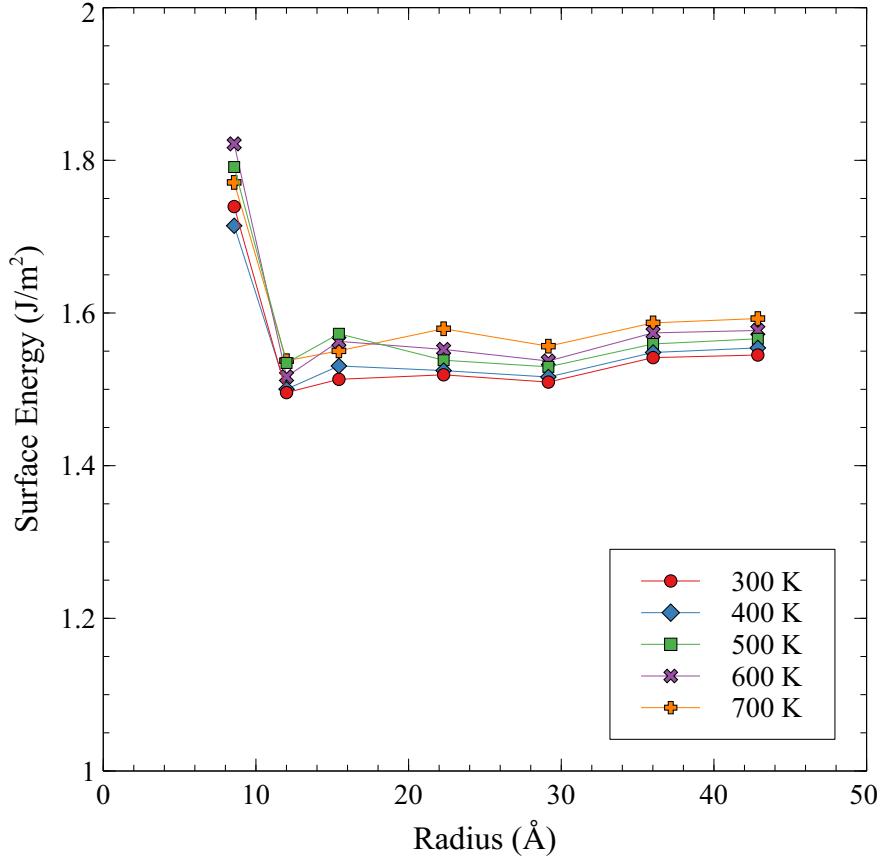

Figure 5: The void surface energy as a function of radius and temperature in U-10Mo.

for all bubble sizes previously mentioned. No restrictions are imposed on the fitting parameters for each individual EOS.

In line with the previous study exploring the EOS of Xe bubbles in U-Mo [14], a Virial equation of state is utilized, expanded to the third order with respect to volume and the second order with respect to temperature, as is shown in equation 11,

$$P = \frac{RT}{v} \left( A + \frac{B}{v} + \frac{C}{v^2} + \frac{D}{v^3} \right) \quad (11)$$

where  $A=1$ , and  $B$ ,  $C$ , and  $D$  are temperature-dependent Taylor series of  $1/T$  ( $B=b_0 + b_1/T + b_2/T^2$ ,  $C=c_0 + c_1/T + c_2/T^2$ , and  $D=d_0 + d_1/T + d_2/T^2$ ), leading to nine unique fitting parameters. The term  $R$  is the gas constant (8.3145 J/mol-K) and  $v$  is the molar volume (cm<sup>3</sup>/mol). The Virial equation is a general function relating pressure, molar volume, and temperature that can be directly derived from statistical mechanics [29].

The subsequent fit, with and without molecular dynamics data, is shown in Fig. 6 and Fig. 7, respectively. The MD data is removed in Fig. 7 and the optimized EOS is displayed on a log/linear scale to emphasize the differences between the individual isotherms. The optimized coefficients are shown in Table 2.

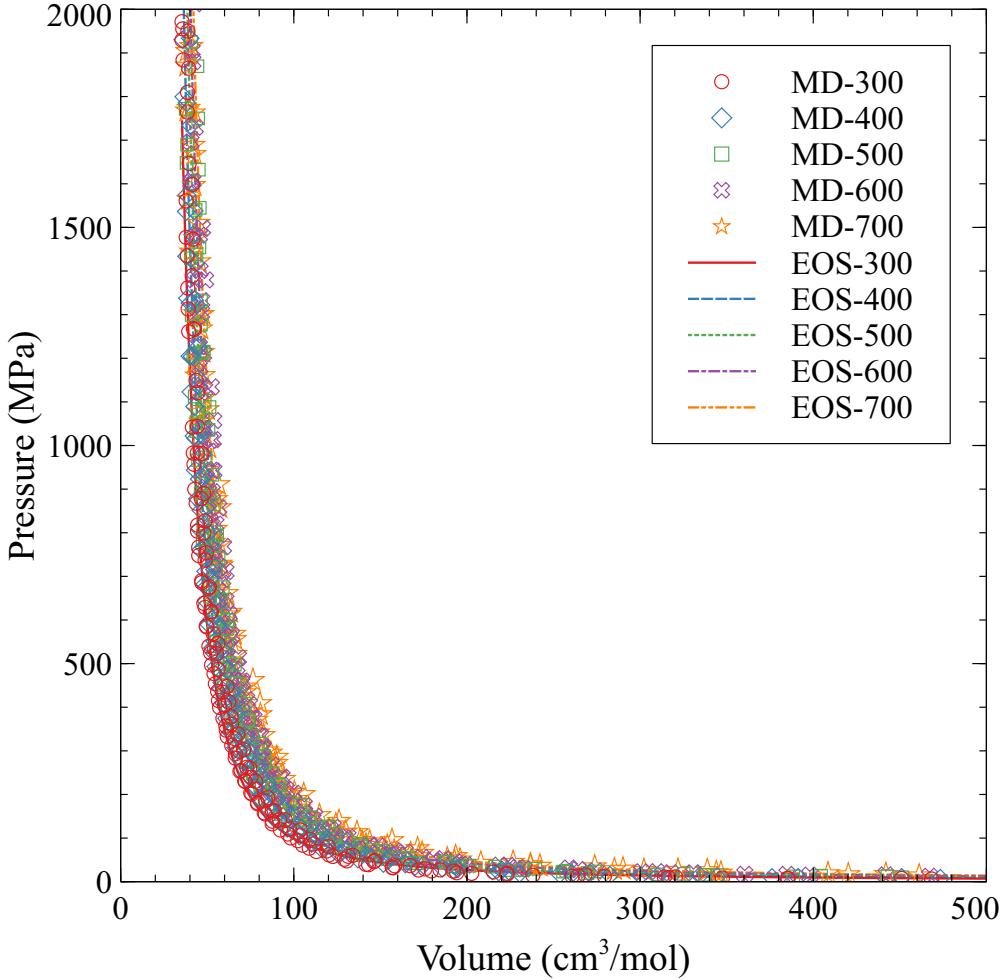

Figure 6: An equation of state (EOS) based on a virial expansion for Xe bubbles in U-10Mo from 400 K to 700 K (a) compared to molecular dynamics data and (b) without molecular dynamics data.

While 4th order optimizations both including and excluding the 3rd order term were pursued, as has recently been performed by Yang [30] for Xe in  $\text{UO}_2$ , the accuracy of the fit to the MD data was not improved. A comparison to the Kaplun EOS [31] is shown in Fig. 8. Kaplun fit a unified EOS for liquid, gas, and fluid defined from thermodynamic equations which shows excellent agreement with experimental data for a number of species. Fig. 8 shows that at low densities, the Kaplun data and the fit to the computational data converge, with the computational EOS predicting a very slightly higher pressure. At high densities and high pressures, there is a dramatic difference between the Kaplun EOS and the Virial EOS from this work, indicating the importance of taking into account the U-Mo matrix for the properties of Xe bubbles. Thus, this updated Virial EOS in equation 11 and Table 2 can be utilized to describe both high and low density/pressure bubbles in U-Mo over the prescribed temperature ranges.

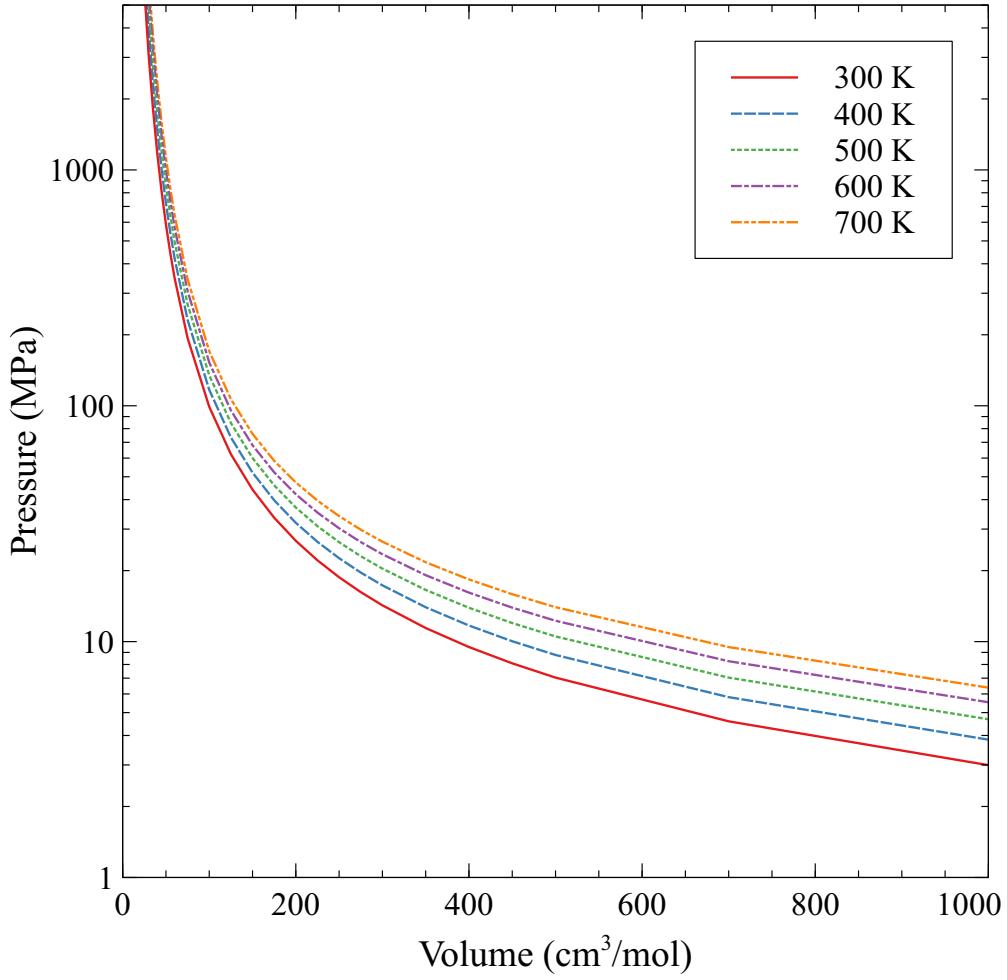

Figure 7: An equation of state (EOS) based on a Virial expansion for Xe bubbles in U-10Mo from 400 K to 700 K (a) compared to molecular dynamics data and (b) without molecular dynamics data.

Table 2: Virial equation of state (Eq. 11) parameters for Xe bubbles in U-Mo.

Parameter	Value
$b_0$	$14.625 \text{ cm}^3/\text{mol}$
$b_1$	$54597.728 \text{ cm}^3\text{-K}/\text{mol}$
$b_2$	$-386.344 \text{ cm}^3\text{-K}^2/\text{mol}$

<sup>220</sup> **4. Conclusions**

In this work, prior interatomic potentials for the U-Mo and the U-Mo-Xe system were reconciled under a single ADP framework, generating a novel ternary potential that utilizes the most accurate descriptions of the individual pair systems which exist. The phase stability of the  $\gamma$  phase of U-Mo was explored via MDMC simulations, demonstrating the inability of prior potential forms to correctly predict the stable solid solution behavior of the alloy. The distortion of the  $\gamma$  phase into a bct structure was analyzed as a function of temperature and composition, agreeing with experimental observations of bcc instability of U-rich systems at lower temperatures. A rigorous approach to vacancy and Xe substitutional energies was applied to this system for the first time, identifying key inaccuracies in previous potential formalisms and providing information on the effect of the local environment on the behavior of Xe substitutionals. Finally, voids and bubbles were explored in U-10Mo, verifying previous studies of void surface energy and providing a new equation of state for Xe bubbles specific to the U-Mo system. This work has served to demonstrate the need for an updated interatomic potential, and provided that tool, which will serve to inform mesoscale and engineering scale fuel performance simulations, providing increased accuracy and reducing known errors, allowing for the exploration of critical phenomena in U-Mo fuels.
